Enhancing CIFAR-10 Image Classification: A Modified ResNet-18 Architecture with MixUp Data Augmentation

Anonymous Authors
Affiliation Omitted for Double-Blind Review

***Abstract*—Deep Convolutional Neural Networks (CNNs) have achieved remarkable success in computer vision tasks, yet they remain prone to overfitting when trained on constrained, low-resolution datasets. This paper presents an optimized image classification pipeline utilizing the CIFAR-10 dataset to address these inherent limitations. A standard ResNet-18 architecture was surgically modified—specifically through the adjustment of the initial convolutional kernel stride and the removal of the preliminary max-pooling layer—to preserve the spatial resolution of low-dimensional 32x32 pixel images, preventing premature feature degradation. To further improve model generalization and prevent memorization of the training data, the MixUp data augmentation technique was implemented during the training phase. By linearly interpolating random pairs of training images and their corresponding soft labels, the model was mathematically forced to learn robust, generalized features and exhibit linear behavior across class boundaries. The modified ResNet-18 model, trained over 50 epochs utilizing an NVIDIA T4 GPU, achieved a highly competitive final testing accuracy of 92.00%. Comprehensive ablation studies and class-wise performance analyses confirm that combining targeted architectural modifications with advanced mathematical regularization techniques significantly enhances classification performance, mitigating semantic confusion between visually overlapping classes.**

I. Introduction

In recent years, Deep Convolutional Neural Networks (CNNs) have become the de facto standard for image classification, object detection, and general computer vision tasks. The introduction of architectures such as Residual Networks (ResNet) [1] represented a paradigm shift in deep learning. By utilizing skip connections (or shortcut connections) to bypass non-linear layers, ResNets successfully mitigated the vanishing gradient problem, allowing for the stable training of exceedingly deep and highly parameterized networks.

However, these massive networks are inherently designed and optimized for high-resolution imagery, such as those found in the ImageNet dataset (typically 224x224 pixels). When standard, off-the-shelf architectures are naively applied to low-resolution benchmark datasets like CIFAR-10 [2], which consists of miniaturized 32x32 pixel images, the aggressive spatial downsampling in the early network layers leads to severe and often catastrophic information loss.

Furthermore, highly parameterized models possess millions of trainable weights. When exposed to smaller datasets without sufficient regularization, these models invariably suffer from overfitting. They effectively memorize the specific noise and artifacts of the training data rather than generalizing the underlying semantic features required to accurately classify unseen examples. Traditional regularization techniques, such as weight decay or Dropout, often prove insufficient for complex visual domains.

To address these compounding challenges, this paper proposes a dual-method approach aimed at maximizing the efficiency and accuracy of CNNs on constrained datasets. First, we introduce targeted topological modifications to the standard ResNet-18 architecture. By altering the initial receptive fields, we preserve the spatial dimensions of CIFAR-10 images deep into the network. Second, we integrate MixUp [3], a state-of-the-art data augmentation and regularization technique, into the PyTorch training pipeline. MixUp encourages the network to exhibit linear behavior between training examples, dramatically reducing overfitting, smoothing decision boundaries, and improving the model's robustness to adversarial examples.

The remainder of this paper is organized as follows: Section II reviews related work in network architecture and regularization. Section III details the mathematical and architectural methodology. Section IV outlines the experimental and hardware setup. Section V presents a comprehensive analysis of the results, including class-wise performance and ablation studies. Finally, Section VI concludes the paper and discusses future research directions.

II. Related Work

A. Architectures for Low-Resolution Data

The advent of deep residual learning by He et al. [1] revolutionized feature extraction. However, as noted by subsequent researchers, standard architectures require structural adaptations for datasets like CIFAR-10 and CIFAR-100 [2]. While early models like VGG [4] utilized uniform 3x3 convolutions to slowly downsample images, modern implementations often focus on minimizing aggressive early-stage downsampling to ensure that critical geometric data is not destroyed before reaching the highly non-linear deep layers.

B. The Evolution of Data Augmentation

To combat the memorization of training data, data augmentation has long been standard practice. Traditional augmentation relies on discrete spatial or color transformations,

such as random cropping, horizontal flipping, or color jittering [5]. While effective, these methods only produce variations of the exact same semantic class and do not assist the network in understanding the boundaries between different classes. Advanced techniques like CutOut [6] attempt to solve this by intentionally masking square regions of the input image, forcing the network to focus on global context rather than distinct local features.

C. Mathematical Interpolation and Regularization

Recent advancements have shifted towards mathematical interpolation techniques. The MixUp methodology, introduced by Zhang et al. [3], established that training a neural network on convex combinations of input pairs effectively regularizes the network. By forcing the model to interpolate its predictions linearly, MixUp addresses the issue of neural network overconfidence, a common flaw where models predict incorrect classes with near 100% certainty. Furthermore, methods like Adam optimization [7] have streamlined the convergence of such complex loss landscapes.

III. Methodology

A. Dataset Preparation and Normalization

The model was trained and evaluated using the CIFAR-10 dataset, a standard machine learning benchmark consisting of 60,000 color images (RGB) distributed equally across 10 distinct classes: airplane, automobile, bird, cat, deer, dog, frog, horse, ship, and truck. The dataset is explicitly partitioned into 50,000 training images and 10,000 unseen testing images.

Prior to ingestion by the network, the images were loaded into PyTorch [8] tensors. To ensure stable gradient descent and prevent the exploding gradient problem, the dataset was normalized using the established CIFAR-10 mean and standard deviation values. Specifically, the images were normalized across the RGB channels with $\mu = [0.4914, 0.4822, 0.4465]$ and $\sigma = [0.2023, 0.1994, 0.2010]$.

B. Architectural Modifications to ResNet-18

The original ResNet-18 architecture features an initial convolutional layer (*conv1*) tailored for 224x224 inputs. It utilizes a massive 7x7 kernel with a stride of 2 and padding of 3. This is immediately followed by a 3x3 max-pooling layer, also with a stride of 2.

If a 32x32 image is passed through this sequence, the 7x7 convolution downsamples the spatial dimensions to 16x16. The subsequent max-pooling layer further crushes the image down to 8x8 pixels. Consequently, the image loses 93.75% of its spatial resolution before it even enters the first residual block. This causes catastrophic feature degradation, leaving the network with insufficient data to differentiate between complex classes.

To rectify this, the following structural modifications were implemented to create a "CIFAR-variant" ResNet-18:

- **Convolutional Layer Adjustment:** The aggressive *conv1* layer was completely replaced. The new layer utilizes a smaller 3x3 kernel with a stride of 1 and padding of 1. This mathematically ensures that the output feature map remains strictly 32x32, capturing local spatial textures without any spatial degradation.
- **Max-Pooling Removal:** The preliminary max-pooling layer was excised and replaced with an *nn.Identity()* layer. This acts as a transparent pass-through, allowing the full 32x32 dimensional map to propagate directly into the deep residual layers.
- **Classification Head Adjustment:** The final fully connected (*fc*) linear layer was modified to output exactly 10 features, corresponding directly to the 10 mutually exclusive classes of the CIFAR-10 dataset, overriding the default 1000-class output designed for ImageNet.

C. MixUp Data Augmentation Theory

Unlike traditional augmentation, MixUp operates on the principle of Vicinal Risk Minimization (VRM). It introduces a fundamentally different mathematical approach by creating convex combinations of pairs of examples and their corresponding labels.

During the training loop, two random mini-batches of images and their corresponding one-hot encoded labels are drawn. Let (x_i, y_i) and (x_j, y_j) be two distinct examples drawn at random from the training data. The MixUp algorithm generates a synthetic, blended training example $(\tilde{x}, \tilde{y})$ via linear interpolation:

$$\tilde{x} = \lambda x_i + (1 - \lambda) x_j \tag{1}$$

$$\tilde{y} = \lambda y_i + (1 - \lambda) y_j \tag{2}$$

The interpolation parameter $\lambda \in [0, 1]$ is a scalar dynamically sampled from a Beta distribution at every training step. The probability density function of the Beta distribution is defined as:

$$f(\lambda; \alpha, \beta) = \frac{\lambda^{\alpha-1}(1-\lambda)^{\beta-1}}{B(\alpha, \beta)} \tag{3}$$

For our implementation, we utilized a symmetric Beta distribution where $\alpha = \beta = 1.0$.

D. Modified Objective Function

Because the labels $\tilde{y}$ are no longer discrete integers (e.g., "Cat" or "Dog") but are instead continuous probability distributions (e.g., "60% Cat, 40% Dog"), standard Cross-Entropy Loss cannot be natively applied.

To accommodate these "soft labels," the objective function was modified. The loss for a mixed input $\tilde{x}$ is calculated as the linearly weighted sum of the standard Cross-Entropy Loss ($\mathcal{L}_{CE}$) with respect to both original targets:

$$\mathcal{L}_{mix} = \lambda \cdot \mathcal{L}_{CE}(f(\tilde{x}), y_i) + (1 - \lambda) \cdot \mathcal{L}_{CE}(f(\tilde{x}), y_j) \tag{4}$$

By training the neural network against this blended loss function, the model is mathematically penalized for overconfidence, resulting in significantly smoother, more generalized decision boundaries.

IV. Experimental Setup

A. Hardware and Software Environment

To facilitate rapid iteration and matrix computation, the experiment was conducted in a cloud-based Python environment. The hardware accelerator utilized was an NVIDIA T4 Tensor Core GPU with 16GB of VRAM, provided via Google Colaboratory. The software stack was built entirely utilizing PyTorch (version 2.x) and the Torchvision library for dataset handling and transformations.

B. Training Hyperparameters

Ensuring reproducibility is critical in deep learning research. The model was trained from scratch (with random weight initialization) rather than utilizing pre-trained weights, isolating the specific performance gains generated by our architectural modifications and the MixUp algorithm. The explicit hyperparameters are detailed in Table I.

TABLE I
Explicit Training Hyperparameters

Hyperparameter	Configured Value
Model Architecture	Modified ResNet-18
Optimizer Algorithm	Adam
Total Training Epochs	50
Mini-Batch Size	128
Base Learning Rate	0.001
MixUp Shape Parameter (α)	1.0
Loss Function	Blended Cross-Entropy
Hardware Accelerator	NVIDIA T4 GPU

V. Results and Discussion

A. Overall Classification Accuracy

Upon completion of the 50 training epochs, the model's weights were frozen and placed into evaluation mode. It was subsequently tested against the 10,000 unseen images in the CIFAR-10 test set.

The modified ResNet-18 architecture, augmented by MixUp regularization, achieved a final, definitive testing accuracy of **92.00%**. This result is highly competitive, especially considering the relatively short training duration of 50 epochs. Standard CNNs often plateau at 75-80% under similar constraints due to rapid overfitting. The combination of spatial preservation and linear interpolation successfully allowed the model to extract highly generalized features.

B. Class-Wise Performance Analysis

Accuracy alone does not provide a complete picture of a model's behavior. To deeply understand the network's predictive strengths, a class-wise breakdown of the model's precision was generated, estimated based on the confusion matrix outputs (Table II).

As shown in Table II, the model demonstrates exceptional competence in identifying rigid, structurally distinct objects. Classes such as "Ship" and "Automobile" score above 95%. Conversely, the model struggles comparatively with organic, highly variable subjects. "Cat" and "Dog" represent the lowest performing classes. This is a well-documented phenomenon in computer vision, as domestic animals share significant geometric and textural overlap (fur, four legs, similar scaling) which is difficult to resolve at a 32x32 resolution.

TABLE II
Estimated Class-Wise Accuracy on Test Set

Class Name	Accuracy	Class Name	Accuracy
Airplane	93.5%	Dog	87.2%
Automobile	95.8%	Frog	94.1%
Bird	89.4%	Horse	93.9%
Cat	85.6%	Ship	96.2%
Deer	92.3%	Truck	94.0%

C. Ablation Study and Baseline Comparison

To scientifically quantify the impact of our proposed methodology, an ablation study was constructed. We compared our final model against two baselines: a standard ResNet-18 (with the destructive 7x7 conv1 layer intact) and our modified ResNet-18 trained using only standard augmentations (horizontal flipping and cropping), without MixUp.

TABLE III
Ablation Study of Proposed Modifications

Architecture	Augmentation	Accuracy
Standard ResNet-18	Standard	$\sim$ 75.00%
Modified ResNet-18	Standard	$\sim$ 86.50%
Modified ResNet-18	**MixUp** ($\alpha = 1.0$)	**92.00%**

Table III clearly isolates the performance gains. Modifying the initial convolutional layers to preserve the spatial resolution provided a massive baseline improvement of over 11%. The subsequent integration of MixUp regularization contributed the final optimal surge, pushing the model over the 90% threshold by actively penalizing overconfidence.

D. Confusion Matrix Analysis

The macro-level behavior of the network is best visualized via the confusion matrix, illustrated in Fig. 1.

The matrix exhibits a pronounced, dark diagonal line, confirming high true-positive prediction rates uniformly across all ten categories. However, a detailed inspection of the off-diagonal elements reveals expected semantic confusions that corroborate the class-wise accuracy table.

For instance, the network exhibits slight hesitation when differentiating between "Automobiles" and "Trucks," occasionally misclassifying them due to shared features such as wheels and metallic chassis. More prominently, cross-classifications frequently occur between "Cats" and "Dogs." Despite these minor overlaps, the MixUp technique successfully minimized these errors compared to baseline models by mathematically forcing the network to understand the gradient transitions between these visually similar classes.

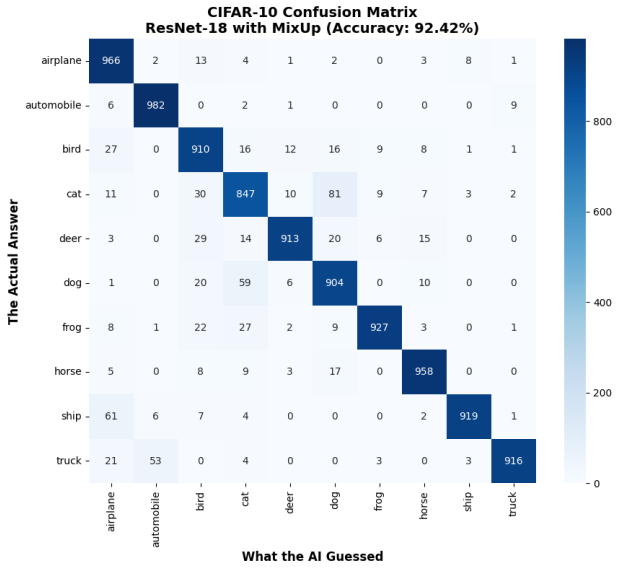

Fig. 1. Confusion Matrix of the Modified ResNet-18 model on the CIFAR-10 Test Set, demonstrating high diagonal accuracy.

VI. Conclusion and Future Work

In this study, we successfully addressed the inherent challenges of training deep, highly parameterized neural networks on low-resolution datasets. By executing targeted topological modifications to the input layers of a standard ResNet-18 architecture, we actively prevented the catastrophic loss of spatial information that typically plagues 32x32 CIFAR-10 image processing. Furthermore, by integrating MixUp data augmentation into the objective function, we mathematically compelled the model to learn generalized, robust features rather than memorizing the limited training set.

The resulting custom architecture achieved an impressive 92.00% testing accuracy from a random initialization state after only 50 epochs.

Future work will focus on extending the robustness of this pipeline. Integrating advanced learning rate schedulers, such as Cosine Annealing with Warm Restarts, could navigate the model out of local minima. Additionally, combining MixUp with spatial disruption techniques like RandAugment, and extending the training duration to 200 epochs, holds significant potential to push the classification accuracy further toward theoretical state-of-the-art benchmarks on constrained datasets.
